## Abstract

Fisheries capture has plateaued, creating ever-greater reliance on aquaculture to feed growing populations. Aquaculture volumes now exceed those of capture fisheries globally<sup>1,2</sup>, with China dominating production through major land-use change; more than half of Chinese freshwater aquaculture systems having been converted from paddy fields<sup>1,3</sup>. However, the greenhouse gas (GHG) implications of this expansion have yet to be effectively quantified. Here we measure year-round methane (CH<sub>4</sub>), nitrous oxide (N<sub>2</sub>O) and carbon dioxide (CO<sub>2</sub>) emissions from paddy fields and new, extensively managed crab aquaculture ponds. The conversion increased associated global warming potentials (GWP) from  $8.15 \pm 0.43$  to  $28.0 \pm 4.1$  Mg CO<sub>2</sub> eq ha<sup>-1</sup>, primarily due to increased CH<sub>4</sub> emission. After compiling a worldwide database of different freshwater aquaculture systems, the top 21 producers were estimated to release  $6.04 \pm 1.17$  Tg CH<sub>4</sub> and  $36.7 \pm 6.1$  Gg N<sub>2</sub>O in 2014. We found that 80.3% of total CH<sub>4</sub> emitted originated in shallow earthen aquaculture systems, with far lower emissions from intensified systems with continuous aeration<sup>4</sup>. We therefore propose greater adoption of aerated systems is urgently required to address globally significant rises in CH<sub>4</sub> emission from the conversion of paddy fields to aquaculture.

With increasing demand for animal proteins due to rising populations and a leveling off in capture fisheries, global aquaculture production has increased by 500% since the late-1980s, and now represents a major global industry<sup>1</sup>. In 2014, aquaculture volume amounted to 101 million tons (Mt) and is projected to reach 230 Mt by 2030, accounting for 62% of global fish and shellfish supply for human consumption<sup>1,2</sup>. This ever-expanding aquaculture sector relies heavily on application of aquafeeds<sup>5,6</sup> which increase nutrient loadings and carbon (C) burial in aquaculture systems and adjacent water bodies<sup>7,8</sup>. Only 25% (11–36%) of the nitrogen (N) consumed by fish was converted to biomass with the remainder excreted into water as un-ionized ammonia<sup>9,10</sup>. Likewise, a substantial proportion of feed C was transformed to CO<sub>2</sub> and CH<sub>4</sub> by animals and microbes<sup>11</sup> or buried in aquaculture systems<sup>7</sup>. In 2016, about 10.9 Tg C and 1.82 Tg N from the 39.9 Mt aquafeeds were estimated to be discharged to environments in global aquaculture<sup>12</sup>. Moreover, fertilizers are widely used in the extensive and semi-intensive aquaculture systems to stimulate phytoplankton production<sup>13</sup>. These intensive C and N loadings have the potential to drive aquaculture systems to become major anthropogenic sources of CH<sub>4</sub> and N<sub>2</sub>O emissions.

Williams & Crutzen<sup>14</sup> tentatively estimated N<sub>2</sub>O emission from the aquaculture sector at 0.09 Tg in 2008, accounting for 0.33% of global N<sub>2</sub>O emission. Using the N<sub>2</sub>O emission factor of influent N (EF<sub>N</sub> = 1.80%) in wastewater treatment plants<sup>15</sup>, global N<sub>2</sub>O emission from aquaculture was estimated to increase from 0.15 Tg in 2009 to 0.60 Tg in 2030, which could contribute 5.72% of global anthropogenic N<sub>2</sub>O emission<sup>10</sup>. However, large uncertainties in these estimates may arise from differences in management levels<sup>16,17</sup> and yield difference between species<sup>17,18</sup>. Besides N<sub>2</sub>O, aquaculture ponds could be important anthropogenic CH<sub>4</sub> sources with characteristics of intensive C loading, shallow water and frequent mixing<sup>19</sup>. To date, >40% of worldwide aquaculture production has been carried out in earthen ponds, while estimates of overall CH<sub>4</sub> budgets in global aquaculture

remain scarce.

China is the world's largest aquaculture producer, contributing ~60% of global volume<sup>1</sup>; furthermore the volume and area of that aquaculture is steadily rising<sup>3</sup>. Above 70% of Chinese freshwater aquaculture production is carried out in extensive and semi-intensive earthen ponds<sup>3</sup>. More and more paddy fields have been, and will continue to be, converted to aquaculture ponds. They currently account for 51.3% of Chinese inland fish ponds<sup>3,18</sup>. There is clearly an urgent need for greater appreciation of the costs associated with GHG emissions incurred during the ongoing unprecedented levels of conversion of paddy fields towards industrial-scale aquaculture.

#### **Effect of conversion of paddy field to aquaculture on GHG emission**

We measured year-round fluxes of CH<sub>4</sub>, N<sub>2</sub>O and CO<sub>2</sub> from three adjacent crab aquaculture ponds converted from paddy fields 12 years ago and neighboring paddy fields (PF) in the Tai Lake basin (31°02'N, 120°25'E; Supplementary Figs. 1 and 2) during 2013–2014. Wheat-rice rotation is the typical cropping system in this region. Urea was applied in PF at 150 and 280 kg N ha<sup>-1</sup> during wheat and rice seasons, respectively. Crab ponds differed in size and water depth (Supplementary Table 1). They were not equipped with aerators but were fertilized during culturing. Chinese mitten crab (*Eriocheir sinensis*) were fed with commercial feed pellets, trash fish and corn seeds at the same rate in each pond during crab production period from March to October. Annual C and N inputs in crab ponds were 1.20 Mg C ha<sup>-1</sup> and 244 kg N ha<sup>-1</sup>, respectively (Supplementary Tables 2–4).

Annual CH<sub>4</sub> emission in PF was 218 ± 7.28 kg CH<sub>4</sub> ha<sup>-1</sup> (Fig. 1a), which was located in the upper end of the previously reported ranges (98.3–240 kg CH<sub>4</sub> ha<sup>-1</sup>) for paddy fields without organic amendment in this area<sup>20</sup>. However, conversion from PF to crab ponds sharply increased

CH<sub>4</sub> emission to  $962 \pm 62$  kg CH<sub>4</sub> ha<sup>-1</sup>; this value was higher than the summarized amount of 572 kg CH<sub>4</sub> ha<sup>-1</sup> in permanently inundated temperate wetlands and the default emission factor (900 kg CH<sub>4</sub> ha<sup>-1</sup>) for tropical inland freshwater wetlands proposed by the Intergovernmental Panel on Climate Change (IPCC; ref. 21).

The CH<sub>4</sub> EF<sub>C</sub> of C inputs from feeds and fertilizer in crab ponds was estimated at up to 60.0% (Table 1), which may be attributed to the enhanced availability of labile organic substrates and highly anaerobic environment in crab ponds. The C output as harvested crab was 0.19 Mg C ha<sup>-1</sup> (Supplementary Table 4), accounting for 16.1% of the C inputs excluding the photosynthates by submerged macrophytes. The remaining 1.04 Mg C ha<sup>-1</sup> was deposited into sediments as unconsumed feed and feces, which led mean dissolved organic C (DOC) concentrations in pond sediments to reach 7.97-fold greater than that of PF (Supplementary Table 1). Additionally, organic compounds in feed remnants and feces such as starch and protein can be more easily decomposed<sup>22</sup> to methanogenic substrates than crop residues in PF. Moreover, pond sediments were permanently inundated, thereby creating anaerobic environments ideal for methanogenesis.

Annual N<sub>2</sub>O emission in PF was  $7.11 \pm 0.23$  kg N<sub>2</sub>O ha<sup>-1</sup> (Fig. 1b). The EF<sub>N</sub> of fertilizer-N applied was 1.05%, closing to the IPCC default value (1.00%) for agricultural soils<sup>23</sup>. Conversion from PF to crab ponds significantly decreased annual N<sub>2</sub>O emission by 95.4% to  $0.33 \pm 0.07$  kg N<sub>2</sub>O ha<sup>-1</sup>, with an EF<sub>N</sub> of  $0.09 \pm 0.02\%$  (Table 1). The lower N<sub>2</sub>O emission in crab ponds was disproportionate to the differences in N application rates (244 vs 430 kg N ha<sup>-1</sup>), let alone the relatively higher total inorganic N content in pond sediments (Supplementary Tables 1). Nitrous oxide is derived from both nitrification and denitrification, although denitrification produces more N<sub>2</sub>O (ref. 24). It is likely that the much lower redox potential (-124 to -160 mV) suppressed nitrification in pond sediments, which reduced overall NO<sub>3</sub><sup>-</sup> concentrations to <1 mg N kg<sup>-1</sup>. This

concentration was lower than the threshold value of 5 mg N kg<sup>-1</sup> for active denitrification<sup>25</sup>. Moreover, the high DOC concentrations and anaerobic conditions permit N<sub>2</sub>O to be further reduced to N<sub>2</sub> through denitrification<sup>26</sup>.

Using the net ecosystem C balance method, annual loss of soil organic C (SOC) in PF was estimated to be 0.04 ± 0.05 Mg C ha<sup>-1</sup> (Table 1), which fell in the range of -0.27 to 0.67 Mg C ha<sup>-1</sup> estimated previously in paddy fields of Tai Lake basin<sup>27</sup>. The CO<sub>2</sub> fluxes measured by transparent chambers in crab ponds were regarded as net ecosystem exchange. On an annual basis, crab ponds were weak net CO<sub>2</sub> sources, releasing 0.13–1.99 Mg CO<sub>2</sub> ha<sup>-1</sup> (Fig. 1c).

Conversion from PF to extensive crab ponds increased the 100-yr GWP from 8.15 ± 0.43 to 28.0 ± 4.1 Mg CO<sub>2</sub> eq ha<sup>-1</sup>, mainly due to increased CH<sub>4</sub> emission with a contribution of 96.3% (Table 1). Our results contrast with those of Liu et al.<sup>18</sup>, who reported such conversion significantly reduced CH<sub>4</sub> and N<sub>2</sub>O emissions by 48% and 56%, respectively. Annual CH<sub>4</sub> emission in Liu's ponds (equipped with aerators and classified as semi-intensive, see below) was just 32.6 kg CH<sub>4</sub> ha<sup>-1</sup> despite the much greater feeding rate and higher sediment DOC concentration compared to test extensive ponds. Hence, substrate availability was not the limiting factor for CH<sub>4</sub> emissions in feeding aquaculture systems, while oxygen exposure by aeration was the key factor affecting CH<sub>4</sub> emissions. Our results highlight that GHG emissions clearly differ from one aquaculture system to another, greatly depending on the intensity of operational management. This observation illustrates the potential for mitigating the effects of future paddy field conversion through careful management.

## Global CH<sub>4</sub> and N<sub>2</sub>O budgets of freshwater aquaculture

Here, we classified aquaculture into four systems: rice-fish, extensive, semi-intensive and intensive

based on local conditions and aquaculture facilities especially whether aerators are used or not (see Methods). We compiled a worldwide database of CH<sub>4</sub> and/or N<sub>2</sub>O emissions that were measured in 45 inland freshwater aquaculture systems during 2003–2015 (Supplementary Table 5). Land-use and production statistics were also compiled for different aquaculture systems of top 21 freshwater aquaculture producers (Supplementary Table 6); however, data from extensive and semi-intensive systems were pooled because of unavailability of aerator-use data for separate classification. In 2014, the top 21 producers contributed 97.5% of global freshwater aquaculture volume<sup>1</sup>.

The synthesized data show that CH<sub>4</sub> fluxes ranged from –0.03 to 37.0 mg CH<sub>4</sub> m<sup>–2</sup> h<sup>–1</sup> in rice-fish, extensive, and semi-intensive systems. Mean CH<sub>4</sub> flux in rice-fish system was the highest at 12.6 ± 3.9 mg CH<sub>4</sub> m<sup>–2</sup> h<sup>–1</sup>, followed by extensive and semi-intensive systems (Fig. 2a). The absence of CH<sub>4</sub> flux in intensive systems can be attributed to a combination of continuous aeration, water exchange and a lack of habitats for methanogens<sup>4</sup>. The rice-fish system also had the highest mean N<sub>2</sub>O flux followed by semi-intensive and extensive systems (28.4 ± 9.8 and 7.56 ± 3.02 µg N<sub>2</sub>O m<sup>–2</sup> h<sup>–1</sup>, respectively; Fig. 2b). The EF<sub>N</sub> and yield-scale N<sub>2</sub>O EF (EF<sub>Y</sub>) in intensive system were 1.16 ± 0.18% and 2.48 ± 0.42 g N<sub>2</sub>O kg<sup>–1</sup> yield, respectively, which were significantly higher than the corresponding values in extensive (0.24 ± 0.10% and 0.66 ± 0.22 g N<sub>2</sub>O kg<sup>–1</sup> yield) and semi-intensive (0.35 ± 0.16% and 0.88 ± 0.41 g N<sub>2</sub>O kg<sup>–1</sup> yield) systems. The EF<sub>Y</sub> in intensive systems was close to the IPCC default EF<sub>Y</sub> (2.66 g N<sub>2</sub>O kg<sup>–1</sup> yield) that is widely used in model estimate for aquaculture<sup>10,21</sup>, but was 2.75- and 1.82-fold greater than that for extensive and semi-intensive systems, respectively. Considering the large volume of extensive and semi-intensive aquaculture (Supplementary Table 6), previous estimates<sup>10,14</sup> of global aquaculture N<sub>2</sub>O emission may have been overestimated because of the higher default EF<sub>Y</sub> mentioned above.

The estimated CH<sub>4</sub> and N<sub>2</sub>O emissions from the top 21 producers in 2014 were 6.04 ± 1.17 Tg

CH<sub>4</sub> and  $36.7 \pm 6.1$  Gg N<sub>2</sub>O, respectively (Table 2), which accounted for 1.82% and 0.34% of global anthropogenic CH<sub>4</sub> and N<sub>2</sub>O emissions, respectively. Methane was a key contributor (94.6%; Fig. 2e) to GWP in freshwater aquaculture, of which  $1.19 \pm 0.27$  Tg CH<sub>4</sub> was emitted from rice-fish system and  $4.85 \pm 1.04$  Tg CH<sub>4</sub> from extensive plus semi-intensive systems. To our knowledge, this is the first global estimate of CH<sub>4</sub> emission from freshwater aquaculture. Our estimated total N<sub>2</sub>O emission was much lower than the previous estimates of 90 Gg N<sub>2</sub>O (ref. 14) and 146 Gg N<sub>2</sub>O (ref. 10) of global aquaculture. Extensive plus semi-intensive systems contributed 87.0% of global volume of freshwater aquaculture, meanwhile, were the largest CH<sub>4</sub> and N<sub>2</sub>O emitter (80.3% and 45.2%, respectively) from this sector. Intensive systems accounted for 8.89% of the production, 27.0% of total N<sub>2</sub>O emissions but negligible CH<sub>4</sub> emissions. Rice-fish systems represented only 4.30% of aquaculture volume, yet they accounted for 19.7% and 27.8% of CH<sub>4</sub> and N<sub>2</sub>O budgets, respectively.

The greenhouse gas intensity (GHGI, GWP/yield) was  $3.59 \pm 0.74$  kg CO<sub>2</sub> eq kg<sup>-1</sup> yield in extensive plus semi-intensive systems, which was 4.46-fold greater than that in intensive systems ( $0.66 \pm 0.11$  kg CO<sub>2</sub> eq kg<sup>-1</sup> yield; Fig. 2f). Therefore, if half of the current productions from extensive plus semi-intensive systems (19.5 Mt) are replaced by intensive systems, the GWP of CH<sub>4</sub> and N<sub>2</sub>O emissions from freshwater aquaculture (excluding rice-fish) will be reduced by 40.1% from 143 Tg CO<sub>2</sub> eq to 85.6 Tg CO<sub>2</sub> eq.

China has emerged as the world's largest freshwater aquaculture emitter of CH<sub>4</sub> ( $4.10 \pm 0.10$  Tg yr<sup>-1</sup>) and N<sub>2</sub>O ( $22.8 \pm 7.1$  Gg yr<sup>-1</sup>), contributing 68.0% and 62.1% of global budgets from the sector, respectively. In China, CH<sub>4</sub> emissions from freshwater aquaculture with  $7.57 \times 10^6$  ha equates to 36.5% of total CH<sub>4</sub> emissions from paddy fields, natural wetlands and lakes ( $11.3$  Tg CH<sub>4</sub> yr<sup>-1</sup>; ref. 28). Since 83.0% of Chinese freshwater aquaculture CH<sub>4</sub> emissions originate from extensive plus

semi-intensive systems, a substantial reduction in emissions could be achieved through improved management practices, such as installing more efficient aerators in earthen ponds and implementing optimized feeding strategies for reducing feed waste.

In conclusion, the conversion of paddy fields to extensive crab aquaculture ponds sharply increased GWP, primarily through a drastic increase in CH<sub>4</sub> release. Our findings emphasize the need to assess the climatic impacts of land-use shifts towards industrial-scale aquaculture. Methane is the most important GHG in freshwater aquaculture compared with N<sub>2</sub>O, and it was primarily sourced from extensive plus semi-intensive systems. Our findings indicate that effective management of extensive and semi-intensive systems through conversion to intensive systems is urgently required to mitigate GHG emissions from the unprecedented growth of aquaculture.

## Methods

**Site description** Field experiments were carried out in a conventional paddy field (PF) and three adjacent crab ponds in the Tai Lake basin (31°02'N, 120°25'E), Suzhou City, Jiangsu Province, China ([Supplementary Fig. 1](#)). This region is characterized by a subtropical monsoon climate with the long-term (1981–2010) mean annual air temperature of 16.5°C and precipitation of 1176 mm (<http://cdc.nmic.cn/home.do>). Paddy fields accounted for 65% of total cropland in this region, however, they are being rapidly converted to aquaculture ponds due to the greater economic benefits from the latter since 1980s ([ref. 31](#)).

Soil was developed from alluvial sediments of the Yangtze River, and classified as stagnic Anthrosols based on the USDA soil taxonomy. The surface soil (0–20 cm) had a pH (H<sub>2</sub>O) of 5.95, bulk density of 1.25 g cm<sup>-3</sup> and a loam texture with 40% sand, 34% silt and 26% clay, and contained 20.3 g kg<sup>-1</sup> organic C and 1.81 g N kg<sup>-1</sup> total N. Three neighboring aquaculture ponds for Chinese mitten crab (*Eriocheir sinensis*) cultivation were converted from paddy fields in 2001.

**Experimental design and field management** Four independent 3 × 8 m<sup>2</sup> plots were established in PF in November 2012. Winter wheat (*Triticum aestivum* L., Yangfumai 4) and summer rice (*Oryza sativa* L., Wuyunjing 23) was rotated during the period from November 2012 to May 2014. During wheat season, urea was applied at the rate of 150 kg N ha<sup>-1</sup>, with basal and supplemental fertilization ratio of 40%:60%. During rice season, urea was applied at the rate of 280 kg N ha<sup>-1</sup>, with the basal and supplemental fertilizer ratio of 50%:50%. Calcium superphosphate (40 and 125 kg P<sub>2</sub>O<sub>5</sub> ha<sup>-1</sup> for wheat and rice, respectively) and potassium sulfate (60 and 125 kg K<sub>2</sub>O ha<sup>-1</sup> for wheat and rice, respectively) were applied as basal fertilizers ([Supplementary Table 2](#)). The row distance was 25 cm for rice and wheat, and the hill distance was 15 cm for rice. No irrigation was

performed during wheat season, while rice was managed under a typical water regime mode of flooding-midseason drainage-reflooding-moist irrigation (F-D-F-M). Crop grain and straw were harvested and oven dried at 60°C until a constant weight.

Parallel field experiments were conducted in three neighboring crab ponds with different size (CP1, 1.71 ha; CP2, 0.71 ha; CP3, 0.09 ha), from March 2013 to March 2014. Monoculture of Chinese mitten crab was employed at the same stocking density of 15000 ind ha<sup>-1</sup> for each pond. The submerged western waterweed (*Elodea nuttallii*) naturally vegetated in ponds and provided molting shelters and foods for crabs. Feeds and fertilizers were applied at the same rates in each pond. Snails (*Bellamya quadrata*) were introduced into the ponds twice at the rates of 600 and 400 kg ha<sup>-1</sup> on April 4 and June 20, respectively, to filter feed residue and provide supplementary foods for crabs (Supplementary Tables 2 and 3). Crabs were fed with commercial feed pellets (2050 kg ha<sup>-1</sup>) (Purina Co. Ltd., Jiaxing, China), trash fish (1250 kg ha<sup>-1</sup>) and corn seeds (1150 kg ha<sup>-1</sup>), twice per day on 9:00 a.m. and 17:00 p.m. until the crabs were harvested. In order to stimulate phytoplankton and waterweed production, cake manure (residue of de-oiled oil seeds) at 40 kg ha<sup>-1</sup> was applied as basal fertilizer while urea, compound fertilizer and calcium superphosphate were applied at the rate of 130, 100 and 200 kg ha<sup>-1</sup>, respectively, with four splits of 25%:25%:25%:25% on March 29, June 5, August 12 and September 27. Annual inputs of C and N to crab ponds were 1.20 Mg C ha<sup>-1</sup> and 244 kg N ha<sup>-1</sup>, respectively. Water was constantly maintained all-year round, while the water depth differed between ponds. Crab harvest started from 1 to 30 October 2013, depending on crab maturity. Crab yield was expressed as fresh weight (Supplementary Table 4). Details management practices in the two systems are shown in Supplementary Table 3.

**Measurement of GHG fluxes** Wooden boardwalks were installed in each plot to facilitate

collecting gas samples and measuring the auxiliary parameters (Supplementary Fig. 2). The static closed chamber technique was used to measure GHG fluxes; in PF, PVC chamber collars (50 cm × 50 cm × 20 cm) with a water-filled channel were inserted into the soil at a depth of 15 cm. In crab ponds, a specially designed system, which included four stainless steel pegs for fixing the system and two adjustable crossbars for elevating or lowering the chamber collars with the fluctuation of water level, were installed along the boardwalks to minimize water wave impact on gas sampling. Three PVC chamber collars were placed on the crossbars in each pond. If necessary, the crossbars together with the chamber collars were adjusted to the best position one day before sampling. The transparent Plexiglass chambers (50 cm × 50 cm × 15 cm) in crab ponds and the stainless steel chambers (50 cm × 50 cm × 50 cm) insulated with white foam in PF were used. See Yuan et al.<sup>32</sup> for further detailed information of the devices.

The GHG fluxes were measured twice weekly in crab ponds during crab production period from March to October and weekly during period without crab production from November to February (Supplementary Fig. 3). In PF, GHG fluxes were measured twice weekly from April to November and weekly from December to March. Gas sampling was conducted at 08:00–10:00 local time to minimize diurnal variation in the flux pattern. During sampling, the chamber was fitted into the water trough of the chamber collars. Each time, four gas samples of the chamber headspace were drawn using a 50-mL syringes at 0, 10, 20, and 30 min after closure and injected into 22-mL pre-evacuated glass vials. Air temperature inside the chamber was simultaneously measured with a mercury thermometer. Concentrations of CH<sub>4</sub>, N<sub>2</sub>O and CO<sub>2</sub> were determined by a gas chromatograph (Agilent 7890, Santa Clara, CA, USA) equipped with a flame ionization detector for CO<sub>2</sub> and CH<sub>4</sub> and a <sup>63</sup>Ni electron capture detector for N<sub>2</sub>O. The gas standards were provided by the National Research Center for Certified Reference Materials, Beijing, China. The precision for GHG

concentrations was  $\pm 0.5\%$  based on repeated measurements of gas standards. The GHG fluxes were calculated using a linear least squares fit to the four points in the time series of concentration for each plot. Data were omitted if the slope of the linear fitting had  $R^2 < 0.90$ . Since the opaque chambers were used in PF, the measured  $\text{CO}_2$  fluxes were ecosystem respiration ( $R_e$ ); in contrast,  $\text{CO}_2$  fluxes in crab ponds measured by transparent chambers were net ecosystem exchange<sup>32</sup>. The dataset of GHG fluxes were supplied as **Supplementary Table 7**.

Annual or seasonal cumulative  $\text{CH}_4$  ( $\text{kg CH}_4 \text{ ha}^{-1}$ ),  $\text{N}_2\text{O}$  ( $\text{kg N}_2\text{O ha}^{-1}$ ) and  $\text{CO}_2$  ( $\text{kg CO}_2 \text{ ha}^{-1}$ ) emissions ( $E$ ) were calculated using the following equation:

$$E = \sum_{i=1}^n (f_i + f_{i+1}) / 2 \times (t_{i+1} - t_i) \times 24 \times 10^{-2}$$

where  $f$  represents the flux of  $\text{CH}_4$  ( $\text{mg CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ ) or  $\text{N}_2\text{O}$  ( $\text{mg N}_2\text{O m}^{-2} \text{ h}^{-1}$ ) or  $\text{CO}_2$  ( $\text{mg CO}_2 \text{ m}^{-2} \text{ h}^{-1}$ );  $i$  is the  $i$ th measurement;  $(t_{i+1} - t_i)$  is the days between two adjacent measurements; and  $24 \times 10^{-2}$  was used for unit conversion.

**Auxiliary measurements** Redox potential of the intact soil and sediment at 10 cm depth was measured *in situ* using a PHB-6 pH/mV meter (Jiaoyuan Instrument, Yancheng, China). The soil of PF or sediment of ponds at 10 cm depth was collected weekly using a Russian corer for mineral N and dissolved organic C measuring. The  $\text{NH}_4^+$  and  $\text{NO}_3^-$  were extracted with 2 M KCl solution (shaken for 1 h and then filtered); extracts were filtered and analyzed on a continuous-flow analyzer (SAN++, Skalar, Breda, the Netherlands). Dissolved organic C was extracted with deionized water (shaken for 30 min at  $25^\circ\text{C}$ , centrifuged for 25 min at 4000 rpm, and filtered through  $0.45\text{-}\mu\text{m}$  membrane filter) and measured on a TOC analyzer (TOC Vcph, Shimadzu, Kyoto, Japan). Soil organic C (SOC) and total N contents were determined by the wet-oxidation redox method and the

Kjeldahl procedure, respectively<sup>33</sup>.

**Estimates of SOC change in paddy field and GWP** The SOC change ( $\delta\text{SOC}$ ) in PF was estimated from the net ecosystem C balance (NECB) using a coefficient of 0.213 for paddy soils in this study<sup>29</sup>, namely, the conversion rate of organic C gain to SOC is  $213 \text{ g C kg}^{-1}$ . The NECB of the short-plant croplands was calculated according to Ma et al.<sup>27</sup>:

$$\text{NECB} = \text{GPP} - \text{Re} - \text{Harvest} - \text{CH}_4 + \text{Manure}$$

where GPP (gross primary production) is inferred from NPP (net primary production) via the NPP/GPP ratio of 0.58 in this region deduced by Zhang et al.<sup>34</sup>; *Re*,  $\text{CH}_4$  and manure are the C exchange through ecosystem respiration,  $\text{CH}_4$  emission, and manure application, respectively; Harvest is the C of removed straw and grain, which was calculated based on biomass yields, and C and N contents in straw and grain (Supplementary Table 4). The NPP includes net primary productions of grain, straw, root, litter and rhizodeposit, according to Ma et al.<sup>27</sup>.

The GWP ( $\text{Mg CO}_2\text{eq ha}^{-1}$ ) in PF is calculated by the following equation<sup>35</sup>:

$$\text{GWP} = 28 \times \text{CH}_4 + 265 \times \text{N}_2\text{O} - 44/12 \times \delta\text{SOC}$$

and for crab ponds:

$$\text{GWP} = 28 \times \text{CH}_4 + 265 \times \text{N}_2\text{O} + 1 \times \text{CO}_2$$

where  $\text{CH}_4$ ,  $\text{N}_2\text{O}$  and  $\text{CO}_2$  denote annual emissions of  $\text{CH}_4$  ( $\text{Mg CH}_4 \text{ ha}^{-1}$ ),  $\text{N}_2\text{O}$  ( $\text{Mg N}_2\text{O ha}^{-1}$ ) and  $\text{CO}_2$  ( $\text{Mg CO}_2 \text{ ha}^{-1}$ ), respectively.

**Data collection and classification of global freshwater aquaculture** As mentioned above, there are large uncertainties in previous model estimates of global aquaculture  $\text{N}_2\text{O}$  emissions by using EFs of applied N and fish yields: First, the  $\text{N}_2\text{O}$  EFs are highly dependent on management levels in the aquaculture system. For example, yield-scale  $\text{N}_2\text{O}$  EF ( $\text{EF}_Y$ ) of carp was  $1.07 \text{ g N}_2\text{O kg}^{-1}$  yield

in an intensive rearing system<sup>16</sup> but was only 0.28 g N<sub>2</sub>O kg<sup>-1</sup> yield in a semi-intensive earthen pond<sup>17</sup>; Secondly, the EF<sub>Y</sub> can be biased by the major yield difference between species. For instance, although the direct N<sub>2</sub>O emission rates in two adjacent semi-intensive aquaculture ponds were comparable, the EF<sub>Y</sub> measured in crab ponds was 8.11-fold greater than that in carp ponds due to the magnitude difference in yields<sup>17,18</sup>.

Here, we compiled a worldwide database of GHG emissions measured in the inland freshwater aquaculture systems (Supplementary Table 5). We identified potential published studies for inclusion in the database using Web of Science with the keywords ‘greenhouse gases or CH<sub>4</sub> or N<sub>2</sub>O’ and ‘aquaculture or fish farming or rice fish or aquaponics’. Twenty-four studies fell within the inland freshwater aquaculture and met the following criteria: (i) field measurement of CH<sub>4</sub> and/or N<sub>2</sub>O emissions was carried out on a per hectare or per fish yield basis; (ii) type of aquaculture system with or without aerator use was reported; (iii) the N input and yield in intensive systems were listed (see below). The dataset include 45 CH<sub>4</sub> and/or N<sub>2</sub>O emission measurements across 19 sites between 2003 and 2015.

Generally, the aquaculture systems are classified based on production per unit volume or per unit area<sup>36</sup>; however, when estimating the regional or global GHG emissions, such classification might be unfit due to lack of the available production data counted by volume or area and deficiency of the cross-species classification criteria for big differences in production performance between culture species. Here, we classified four systems: rice-fish, extensive, semi-intensive and intensive based on the local conditions and aquaculture facilities especially aerator use or not. Actually, the stocking density and production are associated with investment on infrastructure especially aeration equipment<sup>36</sup>, because the dissolved oxygen in fish ponds should be maintained >5.0 mg L<sup>-1</sup>, theoretically<sup>37</sup>.

• Rice-fish systems include integrated rice field or rice field-pond complex and are used to produce fish and other aquatic animals.

• Extensive aquaculture systems involve excavated earthen ponds, irrigation canals and ditches, small lakes and reservoirs used for fish farming. Extensive systems have low stocking density, with natural productivity or limited supplemental feeds and no aerator system.

• Semi-intensive aquaculture systems include excavated earthen ponds, irrigation canals and ditches, small lakes and reservoirs, have higher stocking densities than extensive systems, and are equipped with aerators and managed with artificial feeds and intermittent aeration.

• Intensive aquaculture systems, which utilize man-made rearing units such as concrete/canvas tanks, raceways recirculating systems, have high stocking rates and complete diet management, intensive and continuous aeration, and frequent or continuous water exchange. The cage and pen culture performed in open water bodies like rivers, lakes and reservoirs are also classified as intensive aquaculture because of the high stocking rates and sufficient dissolved oxygen supply from the constant water exchange.

Global inventory of the land use and production statistics are also compiled in different aquaculture systems of the major freshwater aquaculture producers (Supplementary Table 6), however, data of extensive and semi-intensive systems were pooled because of lack of aerator use data to classify each other. Data were derived from the official fisheries statistics for 2014. In case 2014 data were not available, the most recent data were used. If the national official statistical data were not available, the FAO estimate (National Aquaculture Sector Overview) or private survey data were used. Further details on the statistics used are provided in the Supplementary materials.

**Estimation of global CH<sub>4</sub> and N<sub>2</sub>O budgets** We estimated N<sub>2</sub>O emissions from intensive systems

by multiplying  $EF_Y$  by production. Methane emission from intensive systems was recognized as negligible because the aerobic condition limited  $CH_4$  production in such systems<sup>4</sup>. While  $CH_4$  and  $N_2O$  emissions from rice-fish, extensive, and semi-intensive aquaculture systems were estimated by multiplying mean emission rates by area, because (i) the yield EF for  $CH_4$  was generally unavailable in literature; and (ii) the  $EF_Y$  would be biased by the huge yield difference between species in extensive and semi-intensive systems. Additionally, when estimating  $CH_4$  emission from rice-fish systems, the  $CH_4$  fluxes ( $32\text{--}37\text{ mg } CH_4\text{ m}^{-2}\text{ h}^{-1}$ ) measured in Bangladesh<sup>30</sup> were excluded from mean emission rates, because of the extremely high emission rates and relatively small area of rice-fish in Bangladesh ( $\sim 3.97\%$  of global rice-fish area).

It should be noted that our preliminary estimates possess some uncertainties. First, field measurements of  $CH_4$  and  $N_2O$  fluxes were mainly conducted during the feeding period, may result in overestimation of  $CH_4$  and  $N_2O$  emissions; secondly, only averaged  $CH_4$  and  $N_2O$  fluxes in extensive and semi-intensive systems were set up due to the absence of detailed aquaculture facilities data; thirdly, there was no detailed information relative to land use and production in aquaculture in many main producers (e.g. Brazil, Nigeria). More field measurements along with detailed national aquaculture information in those countries are required to obtain more reliable estimates. Moreover, our estimates only focused on the direct  $CH_4$  and  $N_2O$  emissions, however, GHG emission from adjacent water bodies can also be enhanced by the nutrients loading caused by water exchange in some aquaculture systems (especially intensive systems). Hence, these potential indirect emissions should be considered in future estimates.
